

# CptS 355- Programming Language Design

## Functional Programming in Haskell Part 3

**Instructor: Sakire Arslan Ay**  
**Fall 2023**

*World Class. Face to Face.*

Haskell

# Haskell Type Synonyms

- We can create new names for existing types (type synonyms) using:

```
type id = type-definition;
```

- Type synonyms just give another name to an existing type.
- Type synonyms can be used wherever other types are, including inside other type synonyms
- Examples:

```
type Point = (Float, Float)
type Line = (Point, Point)

-- polymorphic type
type Node a = (a,a)
type Edge a = (Node a, Node a)

node1 = (1,2)::(Node Int)
node2 = (4,8)::(Node Int)
node3 = (6,9)::(Node Int)
edge1 = (node1,node2)::(Edge Int)
edge2 = (node2,node3)::(Edge Int)
```

```
type Graph a = [Edge a]
```

```
g = [edge1,edge2]
```

```
(x:xs) = g
```

```
a = fst x
```

```
b = snd x
```

# Haskell Data Type Mechanism

- The data type mechanism specifies new data types using value constructors.
- For example,

```
data Days = Sunday | Monday | Tuesday | Wednesday | Thursday |  
          Friday | Saturday  
          deriving (Show, Eq)
```

```
:t Sunday -- returns Sunday :: Days
```

(optional)

instructs the Haskell compiler to include the new type `Day` into the standard type classes `Show` and `Eq`

- The datatype name and data constructors need to start with capital letters
- See <http://www.haskell.org/onlinereport/derived.html> for other possibilities for 'deriving'

→ What is this data type similar to in C?

# Haskell Data Types – Pattern Matching

- Values of enumeration types are often scrutinized by way of pattern matching
- We include the type's data constructors as patterns in the function:
- For example,

```
isWeekday :: Days -> Bool
isWeekday Sunday    = False
isWeekday Saturday  = False
isWeekday _          = True

isWeekday Tuesday   -- returns True
```

## – Alternative implementation of isWeekday

```
isWeekday :: Days -> Bool
isWeekday day = not (day `elem` [Saturday, Sunday])
```

- If we remove Eq from the deriving type classes, will the second implementation work?

# Haskell Data Types - Parameterized Data Constructors

- The constructors used to define data types may be **parameterized**:

```
data Money = NONE | COIN Int | BILL Int
           deriving (Eq, Show)
```

```
x = (COIN 10)
y = (BILL 20)
z = NONE
:t x           -- returns x::Money
```

- Will the following work?

```
(COIN 5) == (COIN 10)
(COIN 5) == (BILL 5)
(COIN 25) > (COIN 5)
(COIN 25) > (BILL 5)
```

- How should we change the data type definition to make these work?

# Haskell Data Types - Parameterized Data Constructors

- Example function that takes a `Money` value as argument.
  - Calculates the amount of a `Money` value in dollars.

```
amount :: Fractional p => Money -> p
amount (NONE) = fromIntegral(0)
amount (COIN x) = fromIntegral(x)/100.0
amount (BILL x) = fromIntegral(x)
```

→ The parenthesis are necessary

```
amount (COIN 25) -- returns 0.25
```

- We make use of patterns to extract the values of the parameter values of data constructs.
- The following will not work:

```
amount x = if x == COIN then ....
```

```
amount x = if typeof(x) == COIN then ....
```

- How can we write a function that adds two `Money` values ?
- How can we change `amount` function so that it returns a `Money` value (i.e., `COIN`)?

# Haskell Datatype Mechanism

- Data type acts like enum in C.

C enum example:

```
typedef enum {Sunday, Monday, Tuesday, Wednesday, Thursday,  
              Friday, Saturday} days_type;  
days_type firstday= Monday;
```

- Data type with parameterized constructors acts like Union in C.

```
union alt {  
    int x;  
    float y;  
    char *z;  
} *p;
```

# Haskell Polymorphic Data Types

- Consider the following:

```
data MaybeInt = JustInt Int | NoInt deriving (Show, Eq)
data MaybeStr = JustStr String | NoStr deriving (Show, Eq)
data MaybeDouble = JustDouble Double | NoDouble deriving (Show, Eq)
```

- It would be tedious if we had to create such a type and re-name the constructors for each possible base type.
- Polymorphism will be helpful here.
- A user-defined data type may be polymorphic. Which means we can have the type variables in our user-defined types.

# Haskell Polymorphic Datatypes

- Data types (like functions) can be polymorphic.
  - For example:

```
data Maybe a = Just a | Nothing
              deriving (Show, Eq, Ord)
```

- The values of “`Maybe`” type either don’t have a value (which is captured by the `Nothing` construct) or they have a value of some type.
  - Examples:

```
a = (Just 10)      -- :t a returns a :: Num a => Maybe a
b = (Just "ten")   -- :t b returns b :: Maybe [Char]
c = Nothing        -- :t d returns d :: Maybe a
d = (Just [1,2,3]) -- :t e returns e :: Num a => Maybe [a]
```

- The `Maybe` type constructor is pre-defined in Haskell Prelude.

# Haskell “Maybe” Type

- The `Maybe` type constructor is pre-defined in Haskell Prelude.
- Why Haskell introduces an “Maybe” type?
  - In languages like Java or C/C++, object references (or pointers) may be null/undefined.
  - In Haskell, as we have seen, all references to data always point to some value. However, sometimes you need optional-ness. Haskell provides data types in the standard library that allow defining references with optional data.
  - One common use of `Maybe` type is to handle functions with an optional argument.

# Functions with “Maybe” Type

## 1. Head of a list:

```
head' :: [a] -> Maybe a
head' [] = Nothing
head' (x:xs) = (Just x)

head' [[1],[2,3]] -- returns Just [1]
head' []          -- returns Nothing
```

# Functions with “Maybe” Type

## 2. Last element of a list:

```
last' :: [a] -> Maybe a
last' [] = Nothing
last' [x] = (Just x)
last' (x:xs) = last' xs
```

```
last [[1],[2,3]] -- returns Just [2,3]
last [] -- returns Nothing
```

# Functions with “Maybe” Type

## 3. Add two Maybe Int values.

```
addMaybe :: Maybe a -> Maybe a -> Maybe a

addMaybe Nothing Nothing = Nothing
addMaybe Nothing (Just v) = (Just v)
addMaybe (Just v) Nothing = (Just v)
addMaybe (Just v1) (Just v2) = (Just (v1+v2))

addMaybe (Just 20) (Just 10) -- returns Just 30
addMaybe (Just 20) Nothing -- returns Just 20
```

# Data types may be recursive

- Recursive datatypes allow linked structures without explicit pointers.
  - For example:

```
data MyList a = EMPTY | CONS a (MyList a) deriving (Show, Eq)
```

- `MyList` is a data type which is recursive. We will see later that these recursive data types can naturally be processed using recursive functions.
- The type we just defined here is the same type as the Haskell list. Fundamentally there is no difference; they both serve the same purpose. But the compiler recognize them as separate types.

```
:t (:)
(:) :: a -> [a] -> [a]

:t CONS
CONS :: a -> MyList a -> MyList a
```

# Recursive Types

- **Tree data type:**

- A tree consists of a root (maybe all by itself ) and optionally some children which are also trees
- Assume we create a binary `IntTree` where `Int` values are stored in the leaves and no values will be stored in the interior nodes.

```
data IntTree = Leaf Int | Node (IntTree) (IntTree)
              deriving (Show, Eq)
```

```
l1 = Leaf 3
```

```
l2 = Leaf 4
```

```
tree1 = Node l1 l2
```

```
tree2 = Node (Node (Leaf 5) (Leaf 6)) (Leaf 4)
```

Note: `deriving (Show)` is required to print trees.

`deriving (Eq)` is required to compare trees.

# Recursive Types

- **Polymorphic Tree Data Type:**

```
data Tree a = LEAF a | NODE (Tree a) (Tree a)
             deriving (Show, Eq)
```

```
l1' = (LEAF "three");
```

```
l2' = (LEAF "four");
```

```
tree3 = NODE l1' l2'
```

```
tree4 = NODE (NODE (LEAF "one") (LEAF "two"))
             (NODE (LEAF "three") (LEAF "four"))
```

Now we can create trees of various types.

# Recursive Types

- **Alternative Tree Types:**

1. Polymorphic ternary tree, values are stored only in the leaves

```
data TriTree a = TLEAF a | TNODE (TriTree a) (TriTree a) (TriTree a)
               deriving (Show, Eq)
```

```
ttree = TNODE (TLEAF 9)
              (TNODE (TLEAF 8) (TLEAF (-1)) (TLEAF 7))
              (TNODE (TLEAF 3) (TLEAF 4) (TNODE (TLEAF 1)
                                                  (TLEAF (-8))
                                                  (TLEAF 5) ))
```

2. Polymorphic binary tree, values are stored both in leaves and the interior nodes

```
data BinTree a = BLEAF a | BNODE a (BinTree a) (BinTree a)
```

```
btree = BNODE "one" (BLEAF "two")
        (BNODE "three" (BLEAF "four") (BLEAF "five") )
```

# Functions to Process Recursive Types

- We can use recursive functions to process the values in recursive tree types.

```
data Tree a = LEAF a | NODE (Tree a) (Tree a)
             deriving (Show, Eq)
```

- There is a strong connection between the structure of the recursion and the structure of the recursive data type.
- Example:
  - Function to count the number of leaves in a tree:

```
nLeaves :: Num p => Tree a -> p
nLeaves (LEAF _) = 1
nLeaves (NODE t1 t2) = (nLeaves t1) + (nLeaves t2)
```

```
myTree = NODE (NODE (LEAF "one") (LEAF "two")) (NODE (LEAF "three") (LEAF "four"))
nLeaves myTree --returns 4
```

# Functions to Process Recursive Types

```
data Tree a = LEAF a | NODE (Tree a) (Tree a)
             deriving (Show, Eq)
```

## - Copy tree:

```
copyTree :: Tree a -> Tree a
copyTree (LEAF x) = LEAF x
copyTree (NODE t1 t2) = NODE (copyTree t1) (copyTree t2)
```

```
myTree = NODE (NODE (LEAF "one") (LEAF "two")) (NODE (LEAF "three") (LEAF "four"))
copyTree myTree
--returns NODE (NODE (LEAF "one") (LEAF "two")) (NODE (LEAF "three") (LEAF "four"))
```

# Functions to Process Recursive Types

```
data Tree a = LEAF a | NODE (Tree a) (Tree a)
             deriving (Show, Eq)
```

## - Tree Map:

```
treeMap :: (t -> a) -> Tree t -> Tree a
treeMap op (LEAF x) = LEAF (op x)
treeMap op (NODE t1 t2) = NODE (treeMap op t1) (treeMap op t2)
```

```
myTree = NODE (NODE (LEAF "one") (LEAF "two")) (NODE (LEAF "three") (LEAF "four"))
strUpper s = map toUpper s    --should import Data.Char
treeMap strUpper myTree
--returns NODE (NODE (LEAF "ONE") (LEAF "TWO")) (NODE (LEAF "THREE") (LEAF "FOUR"))
```

# Functions to Process Recursive Types

```
data TriTree a = TriLEAF a |  
                TriNODE a (TriTree a) (TriTree a) (TriTree a)  
                deriving (Show, Eq)
```

## - Preorder Traversal:

```
preOrderTri :: TriTree a -> [a]  
preOrderTri (TriLEAF x) = [x]  
preOrderTri (TriNODE x t1 t2 t3) = [x] ++ (preOrderTri t1) ++  
                                     (preOrderTri t2) ++ (preOrderTri t3)
```

```
myTriTree = TriNODE 0 (TriNODE 9 (TriLEAF 1) (TriLEAF 2) (TriLEAF 6) )  
                (TriNODE 8 (TriLEAF 3) (TriLEAF 4) (TriLEAF 7) )  
                (TriLEAF 5)  
preOrderTri myTriTree  
  
--returns [0,9,1,2,6,8,3,4,7,5]
```
